1. Introduction

[2] Dynamic process of coronal mass ejections (CMEs) in the heliosphere is key information for us to evaluate the CMEs’ geo-effectiveness. But it becomes more complicated when successive CMEs interact in the heliosphere. Both observational and numerical studies have shown that a CME’s shape, velocity, and direction may change significantly through collisions and interactions [e.g., Wang et al., 2002, 2003, 2005, Reiner et al., 2003; Farrugia and Berdichevsky, 2004; Lugaz et al., 2005, 2009, 2012; Hayashi et al., 2006; Xiong et al., 2007; Wu et al., 2007; Liu et al., 2012; Temmer et al., 2012; Shen et al., 2012; C. Shen et al., 2012].

[3] The CMEs are magnetized plasmoids. In most cases, CMEs could be treated as an elastic ball in the heliosphere due to low reconnection rate, and the collision between them was usually thought to be elastic or inelastic, through which the total kinetic energy of colliding CMEs conserves or decreases. This classic collision picture was often used to analyze the momentum exchange during CME collisions [e.g., Lugaz et al., 2009; Temmer et al., 2012]. But the picture sometimes failed to explain observations. For example, the analysis of 1 August 2010 CME-CME interaction event suggested that the collision between CMEs is unlikely to be elastic or perfectly inelastic [Temmer et al., 2012]. A possible explanation is that the CME-driven shock if any may be involved in the momentum transfer [Lugaz et al., 2009]. Another explanation can be found in a most recent work about the CME-CME interaction event during 2–8 November 2008 by C. Shen et al. [2012], which for the first time revealed that the collision of CMEs could be superelastic. A fundamental definition of superelastic collision is that the total kinetic energy of colliding system increases after the collision. It is unexpectedly beyond the classic collision picture, but well explains the observed track of the leading CME in that event.

[4] If superelastic collision does happen, the CME’s effect on space weather needs to be re-evaluated because more thermal and magnetic energy inside CMEs will be converted into kinetic energy, which may cause the changes of the direction and velocity of CMEs to be different from usually expected. However, at present, the finding of superelastic is doubtable, because the result was obtained based on the remote imaging data from STEREO spacecraft and some highly ideal assumptions. Thus, a numerical simulation may favor us validating the possibility of CMEs’ superelastic collision.

[5] In this letter, we carry out three-dimensional (3-D) MHD simulations based on the observations of the 2008 November event and try to reveal the nature of the CMEs’ collision through the analysis of the energy transformation during the collision. In the next section, the MHD model and simulation method are introduced. The simulation results of the CMEs’ collision and a comparison with a non-collision case are presented in sections 3 and 4, respectively. In the last section, a summary and discussion is given.

2. MHD Model and Simulation Method

[6] The numerical scheme we used is a 3-D corona-interplanetary total variation diminishing (COIN-TVD) scheme in a Sun-centered spherical coordinate system ($r, \theta, \varphi$) [Feng et al., 2003, 2005; Shen et al., 2007, 2009]. The projected characteristic boundary conditions [Wu and Wang, 1987; Hayashi, 2005; Wu et al., 2006] are adopted at the lower boundary. The computational domain is set to cover $1 R_s \leq r \leq 100 R_s$, $-89^\circ \leq \theta \leq 89^\circ$ and $0^\circ \leq \varphi \leq 360^\circ$, where $r$ is the radial distance from solar center in units of solar radius $R_s$ and $\theta$ and $\varphi$ are the elevation and azimuthal angles, respectively.

[7] We first establish a steady state of background solar wind. The potential field, extrapolated from the observed
line-of-sight magnetic field on the photosphere, and Parker’s solar wind solution are used as the initial magnetic field and velocity. The initial density is deduced from the momentum conservation law, and the initial temperature is given by assuming an adiabatic process. With these initial conditions, our MHD code may quickly reach a self-consistent and steady state of solar wind. Figure 1 presents the radial velocity of background solar wind and magnetic field lines, which shows the typical characteristics, e.g., nearly axisymmetric and dipolar, at solar minimum.

As we did in the previous work, two CMEs are modeled as magnetic blobs [Chané et al., 2005; Shen et al., 2011] and introduced successively with a separation time of 6 h and their centers sitting at \( r = 2 \) \( R_s \). Hereafter, we use CME1 and CME2 for the first and second initiated CMEs. To reproduce the 2008 November event, two key parameters, their initial propagation directions and velocities, are chosen to be the same as those derived from observations [C. Shen et al., 2012]. The directions of the two CMEs are N06W28 and N16W08, respectively, and the propagation speeds are 243 and 407 km s\(^{-1}\), respectively. Another important parameter, plasma beta, is set a reasonable value of 0.06 for both CMEs. According to the analysis of errors in C. Shen et al. [2012], other parameters are not pivotal and therefore set arbitrarily. Table 1 lists the initial parameters of the two CMEs.

### Simulation Results

The background solar wind between the directions of the two CMEs gradually increases from about 316 km s\(^{-1}\) at 18 \( R_s \) to about 433 km s\(^{-1}\) at 100 \( R_s \). Due to the expansion, the leading edges of the two CMEs move faster than ambient solar wind. Thus, we locate the CMEs by simply setting a threshold of 450 km s\(^{-1}\) in the map of radial velocity.

Since CME2 is faster than CME1, the two CMEs get closer and closer as shown in the three panels. The momentum transfer could be clearly seen by noting the orange region. At 7 h, right before the collision, the orange region, which denotes a radial velocity of 600 km s\(^{-1}\), locates in CME2. After the two CMEs touch, the orange region moves forward, which suggests a momentum transfer from CME2 to CME1.

With some limits of the MHD code, however, we cannot identify the exact boundary of a CME. Thus, we do not analyze the momentum or energy change for individual CMEs, but instead, analyze the variations of all kinds of energies integrated over the whole computational domain. All the energies of the two CMEs and solar wind at initial time are shown in Table 1. Although the energy of the two CMEs is only about 5% of the total energy of background solar wind, it is larger than the errors unavoidably from numerical calculations and ideal MHD assumptions as will be seen below.

\(^{a}\)The columns from the second one to the right are the propagation direction, velocity, number density, temperature, magnetic field, plasma beta, radius, and the kinetic, magnetic, thermal, gravitational and total energies, respectively. The values of the velocity of solar wind are at \( r = 18 \) and 100 \( R_s \), respectively, in the direction of N11W18. The energies of solar wind are the integration over the whole computational domain before CMEs are introduced.
where the magnetic energy, $E_m$, and thermal energy, $E_t$, both decrease. The changes of these energies are all one order larger than the variation of total energy, suggesting a real physical process. The increase of $E_t$ is due to the CMEs carrying heavier plasma than the background solar wind. The changes of other energies are consistent with the well-known picture that the CME’s magnetic and thermal energy will be converted into kinetic energy as it expands during the propagation [e.g., Kumar and Rust, 1996; Wang et al., 2009].

In order to validate that the kinetic energy gain (or partial of it) comes from a superelastic collision, we need another case for comparison, in which the two CMEs do not collide. To do this, we adjust the longitude of CME2 to 165°E, which causes the longitudinal separation between the two CMEs to be 175°, and keep all the other parameters exactly the same as those in the case of collision. Hereafter we use Case 1 for collision, Case 2 for non-collision and CME2′ for the second CME in Case 2. Figure 1 has shown that the background solar wind and magnetic structure around CME2 and CME2′ are quite similar. We believe that the two cases are comparable.

4. Comparison Between the Cases of Collision and Non-collision

From CME1 being introduced into computational domain to the instance of CME2 being introduced, the two cases are exactly the same. After CME2 is introduced, the two cases become different. The dashed blue lines in Figure 3 show the energy variations for Case 2, which are similar to those in Case 1 except some small differences. These small differences are shown much clearly in Figure 4.

The difference of the total energy, $\Delta E_i$, between the two cases has small fluctuations with an amplitude of about $2 \times 10^{29}$ erg. It indicates the level of numerical error. The difference of the gravitational energy, $\Delta E_g$, is about $10^{29}$ erg, smaller than the numerical error. Thus, we cannot conclude if $\Delta E_g$ is real or not. For all the other energies, the differences are significantly larger than the error and thought to be physically meaningful.

It is found that from the time of $t = 7$ h, the difference of the kinetic energy, $\Delta E_k$, rapidly increases from about $2 \times 10^{29}$ erg to about $1.4 \times 10^{30}$ erg in 2 h, and then decreases back to about $10^{30}$ erg and slowly returns. It means that there is extra kinetic energy gain in Case 1. Recall that the energy flow across the boundaries has been deducted, and therefore the extra kinetic energy gain must come from the collision of the two CMEs. Although we do not know the kinetic energy for each CME, the comparison between Case 2 and Case 1 is just like the comparison between the state before and after the collision. The significant difference between the two cases in the kinetic energy does confirm that the collision of CMEs could be superelastic as suggested by C. Shen et al. [2012].

It is hard to identify when the collision ends. It might be at $t = 20$ h or even later. But we are sure that the two CMEs have fully interacted for a long time. This long process allows magnetic and thermal energies to be converted into kinetic energy. It is noticed that the decrease of the magnetic energy is much larger than that of the thermal energy, which suggests that the magnetic energy stored in CMEs is the major source of the extra kinetic energy gain.

Figure 2. Radial velocity map of the two CMEs at the time of 7, 10, and 15 h. The surfaces of the radial velocity being 450 and 600 km s$^{-1}$ are displayed by different colors. Some magnetic field lines are shown as the thick white lines. The small blue ball shows the position and size of the Sun.
5. Summary and Discussion

[19] We have comparatively investigated the energy variation during the collision of two successive CMEs. It is found that the kinetic energy gain in the case of collision is larger than that in the case of non-collision though the initial conditions of the two CMEs and the background solar wind are exactly the same. This result does suggest that the collision between the two CMEs is superelastic, through which additional magnetic and thermal energies are converted into kinetic energy.

[20] In this study, the initial kinetic energy of the two CMEs is about $3.38 \times 10^{30}$ erg (see Table 1). Since the collision happens quickly after the introductions of the CMEs, we may use this value approximately as the CMEs' kinetic energy right before the collision. The extra kinetic energy gain due to the collision is on the order of $10^{30}$ erg. It is therefore derived that the superelastic collision of the two CMEs causes their total kinetic energy increased by about 3–4%, which is close to the value of 6.6% given by C. Shen et al. [2012]. Assuming the energy gain totally goes to CME1, we then estimate that the kinetic energy of CME1 increases by about 13%. Normally, the leading CME will be accelerated and the trailing CME decelerated [e.g., Wang et al., 2005; Shen et al., 2012; Lugaz et al., 2012]. Thus, the percentage of the kinetic energy gain of CME1 should be even higher. In terms of velocity, CME1 is speeded up by at least 6%, i.e., 15 km s$^{-1}$. This number is not large enough to impact the space weather forecasting. But a comprehensive investigation of the effect of collision on the velocity and direction of CMEs is still worth being pursued.

[21] In this letter, we only consider the CMEs similar to the 2008 November event. It is not clear if the collision between any CMEs is superelastic. Moreover, some open questions remain. For example, how are the magnetic or thermal energies convert into kinetic energy? How does magnetic reconnection influence the collision process and result if it efficiently occurred? Another interesting thing is that the 2010 August event studied by Temmer et al. [2012]...
might be a case of “super-inelastic” collision, a process somewhat like merging, of two fast CMEs. How and why could it happen? All these questions are worthy of further studies.
